# 1 Modelling of ex-post impacts using PRIMES

## 1.1 Introduction

This report provides the results from the application of a modified version of the PRIMES model for the ex-post evaluation of selected EU climate change policies and measures. This work enables the identification of the key drivers of energy-related emissions of CO<sub>2</sub> with the EU between 2000 and 2005, as well as alternative estimates of the ex-post savings arising from selected policies.

The PRIMES model has been used on a stand-alone basis i.e. it has not been explicitly linked with the data or methods applied elsewhere in the project. However, the results from the PRIMES model have been compared with the results from the other ex-post evaluation methodologies in the main project report. This includes some discussion of the comparability of the results.

### 1.1.1 Scope and objectives

The objective of the PRIMES model analysis was twofold:

- to decompose the observed evolution of energy related CO<sub>2</sub> emissions over the period 2000-2005
- to analyse the impacts of selected EU policies and measures (PAMs) on this evolution.

A number of different case study PAMs have been analysed, as have a number of different energy sub-sectors. For each of the main energy sub-sectors the trend in CO<sub>2</sub> emissions between 2000 and 2005 has been decomposed so as to reflect:

- technological progress,
- structural changes in the EU economy,
- changes in international fuel prices and the implementation of EU PAMs.

The approach to the decomposition analysis is described further below.

## 1.2 Overview of the PRIMES model

The PRIMES model simulates a market equilibrium solution for energy supply and demand. The equilibrium is determined by finding the prices of each energy form such that the quantity producers find best to supply matches the quantity consumers wish to use. The model is behavioural but it also represents in an explicit and detailed manner the available energy demand and supply technologies and pollution abatement technologies. The system reflects considerations about market economics, industry structure, energy/environmental policies and regulation. These are conceived so as to influence market behaviour of energy system agents. The modular structure of PRIMES reflects a distribution of decision making among agents (sectors and sub-sectors) that decide individually about their supply, demand, combined supply and demand, and prices. The market integrating part of PRIMES simulates market clearing.

### 1.2.1 Model structure

The model is organised by energy production sub-systems (oil products, natural gas, coal, electricity and heat production, others) for supply and by end-use sectors for demand

(residential, commercial, transport, nine industrial sectors). Some demanders may be also suppliers, as for example industrial co-generators of electricity and steam.

Several end-uses and processes are distinguished:

- (a) 11 industrial sectors, subdivided into 26 sub-sectors using energy in 12 generic processes (e.g. air compression, furnaces);
- (b) 5 tertiary sectors, using energy in 6 processes (air conditioning, office equipment);
- (c) 4 dwelling types using energy in 5 processes and 12 types of electrical durable goods (e.g. refrigerator, washing machine, television);
- (d) 4 transport modes, 10 transport means and 10 vehicle technologies, 14 fossil fuel types, 4 new fuel carriers (e.g. hydrogen, methanol, bio-fuels) 10 renewable energy types;
- (e) several supply sub-systems: power and steam generation, refineries, gas supply, biomass supply, hydrogen supply (not used in this project), primary energy production. The power generation sub-model represents 150 power and steam technologies, the electricity grid with import and export links in the EU internal energy market and details of load curves (typical days and hours) for electricity and steam;
- (f) 7 types of pollutants emitted from energy processes and a series of associated policy instruments, including emission trading schemes.

### **1.2.2 Data sources**

The model's database includes historical data, on which the model is calibrated. The present database covers 1990-2000 and 2000-2005. The main PRIMES data input sources are the following:

- NEW CRONOS – EUROSTAT: energy balance sheets (as available in June 2007); macroeconomic data; population data and projections; fuel prices data
- Various technology databases developed under EC programs:
  - MURE, ICARUS, ODYSSEE for demand sectors
  - SAPIENTIA, TECHPOL for supply technologies
- NEMS model database (US DOE)
- IEA database: fuel prices
- EPIC database: detailed data on existing power plants and their use
- UNIDO data and Industrial associations data (industrial statistics)
- Various surveys and qualitative information
- Specifically commissioned studies

### **1.2.3 Model coverage and output**

The model simulates the European energy system and markets on a country-by-country basis and provides detailed results on energy balances, CO<sub>2</sub> emissions, investment, energy technology penetration, prices and costs by 5-years intervals over a time period from 2000 to 2030.

The model produces results for 2000 and 2005 as calibrated years. This means that all existing policy effects (e.g. RES-E directive, Biofuels directive, ACEA agreements, CHP directive, Buildings directive) have been appropriately quantified under PRIMES Baseline assumptions so as to reproduce the observed statistics. Results for year 2010 and beyond (up to 2030) are considered as projections (scenario years).

## **1.3 Methodological approach**

In order to perform a quantitative analysis of the effects of selected EU PAMs to date, as well as to identify the role of other key socio-economic parameters (e.g. international fuel prices)

on the evolution of CO<sub>2</sub> emissions between 2000 and 2005, it was necessary to develop a modified version of the PRIMES model. To estimate the ex-post impacts to date the year 2005 can no longer be treated as a calibrated year, as is the case with the current model, since the results would not change for 2005 regardless of the policies analysed. Instead 2005 is made a projection year for which results are calculated by the model (allowing for deviation from observed statistics) on the basis of the assumptions introduced. In this context a number of alternative policy cases could be defined by altering different model assumptions.

However, when performing some test runs using 2005 as a projection year, and without altering any model assumptions compared to those introduced in the Baseline scenario (i.e. in the presence of existing policies and measures), it was found that the deviation of results for 2005 from observed statistics was in some cases significant. Therefore, a new version of the PRIMES model was developed, in which a number of model behavioural parameters were revised and adjusted (on a country by country basis) so that the projections for 2005 under the Baseline assumptions do not deviate from observed statistics. This provided a more sound basis for the analysis of the alternative policy cases.

### 1.3.1 Decomposition analysis

The PRIMES model was used to provide a detailed decomposition of the observed development of energy related CO<sub>2</sub> emissions over the period 2000-2005.

Decomposition analysis is a method that allows a better understanding of the role of different separate developments, that occur simultaneously, and have an impact on the evolution of the parameter in focus (in our case energy related CO<sub>2</sub> emissions). The *decomposition method* starts from the situation in which no effect besides the growth in activity level is included ("frozen efficiency") in the analysis, and then calculates what the emissions are if only effect A had occurred, and then if effects A and B had occurred, etc. With this method, every effect is compared against a different baseline. The baseline of effect A is "frozen efficiency", the baseline of effect B is "the frozen efficiency + effect A", etc.

The following drivers were examined as part of the decomposition analysis:

- Activity changes: changes related to economic and demographic developments
- Structural changes: changes related to shifts in the structure of the EU economy (e.g. shifts away from primary and secondary sectors and towards services and high value added products) as well as behavioural changes arising from economic growth (e.g. increasing aviation and private cars activity occurring to the detriment of public transport means)
- Energy intensity changes: changes related to technology improvements taking place in the EU energy system
- Changes in the fuel mix: changes related to the development of fuel prices as well as technology developments (e.g. increasing competitiveness of natural gas fired power plants) and behavioural patterns (e.g. increasing use of electric appliances in the residential and tertiary sectors)

Starting from the "Frozen case" scenario, i.e. a scenario which reflects a situation in which no effects besides economic activity growth and demographic developments are taken into account, a number of alternative cases were examined. These included differentiated assumptions for one or more of the following drivers:

- Structural changes of the EU economy
- Technology characteristics
- Fuel prices and taxation policies
- Implementation of EU PAMs

The results obtained from the different cases (including the Baseline scenario which reflects the "real world") were then combined and analysed, through a meta-model specifically developed for the purpose of the project, in order to decompose the CO<sub>2</sub> emissions

developments over the period 2000-2005. The decomposition was performed both at the aggregate and the sectoral energy system level, and for each Member State separately. It should be noted that the decomposition results may differ for different levels of disaggregation. For example, decomposition results per industrial sector do not sum up to the corresponding decomposition results for total industry. This is explained by the fact that whereas for total industry the development of sectoral value added is used as the activity indicator, for specific industrial sectors the activity indicator relates to production levels of the different industrial processes involved (e.g. integrated steelworks versus electric arc processing production in the iron and steel industry).

The decomposition at the level of total final energy demand is obtained by summing up demand sector totals. The same is the case with regards to the decomposition at the level of the total energy system which is obtained by summing up total final energy demand, power generation, district heating and energy branch (for which only distinction between activity growth and changes in the fuel mix is possible).

### **1.3.2 Evaluation of policy impacts**

In addition to decomposing the impact of the key socio-economic drivers upon CO<sub>2</sub> emissions, the PRIMES model was also used to quantify the impacts of three selected EU PAMs. As with the decomposition analysis, the modelling assumed that the parameters reflecting the corresponding effects remain as in 2000. These following three cases were examined:

- A case analysing the effects of the voluntary agreement with car manufacturers;
- A case analysing the effects of the Biofuels Directive; and,
- A case analysing the effects of the RES-E directive

The results obtained from the PRIMES model, for each of the policies considered, can be compared to the results from the alternative evaluation methodologies. This provides a cross-check of the results, and also provides some insights into the importance of certain effects that cannot be easily be captured with bottom up methods (e.g. impact of price signals).

The results of the PRIMES modelling can therefore be used to:

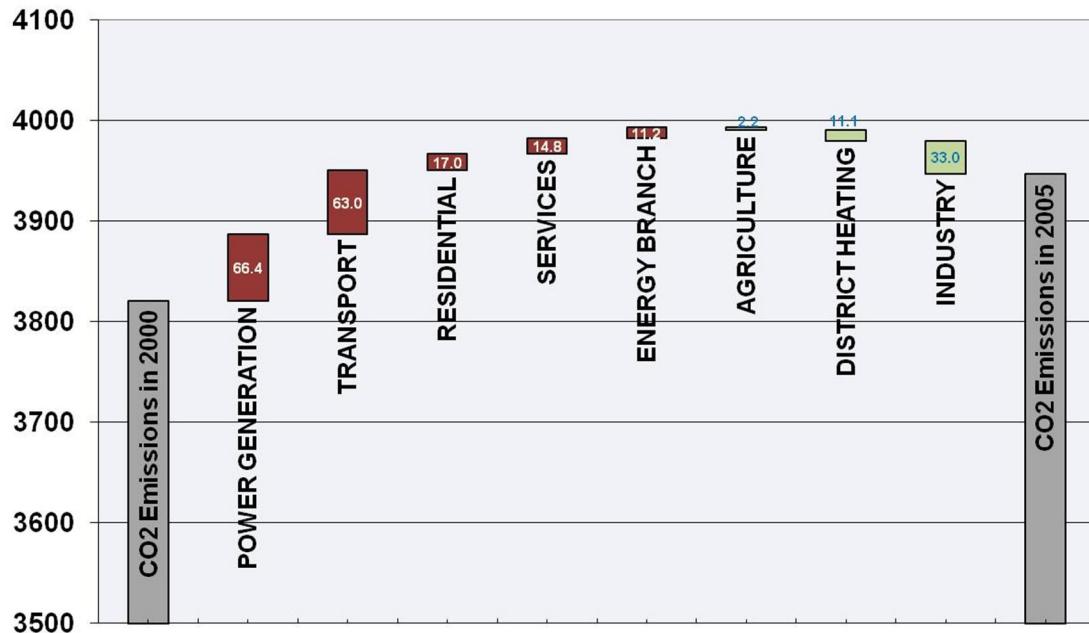

- refine the alternative methodologies (if needed);
- identify the areas where sensitivity analysis is required; and,
- validate the findings from the alternative methodologies.

In addition, the outputs from the PRIMES analysis provide an indicative estimate of the impacts within those Member States not covered by the other methodologies.

## 1.4 Drivers of emissions in EU-27: decomposition analysis for 2000 to 2005

Between 2000 and 2005 energy related CO<sub>2</sub> emissions in the EU27 energy system increased from 3,820 Mt CO<sub>2</sub> to 3,947 Mt CO<sub>2</sub> (+126.2 Mt CO<sub>2</sub> or +3.3%). As illustrated in Figure 1 power generation and the transport sector were the main drivers for this increase of CO<sub>2</sub> emissions whereas the most pronounced decline of CO<sub>2</sub> emissions was observed in industry.

Figure 1: CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development in the EU27 energy system (2000-2005)

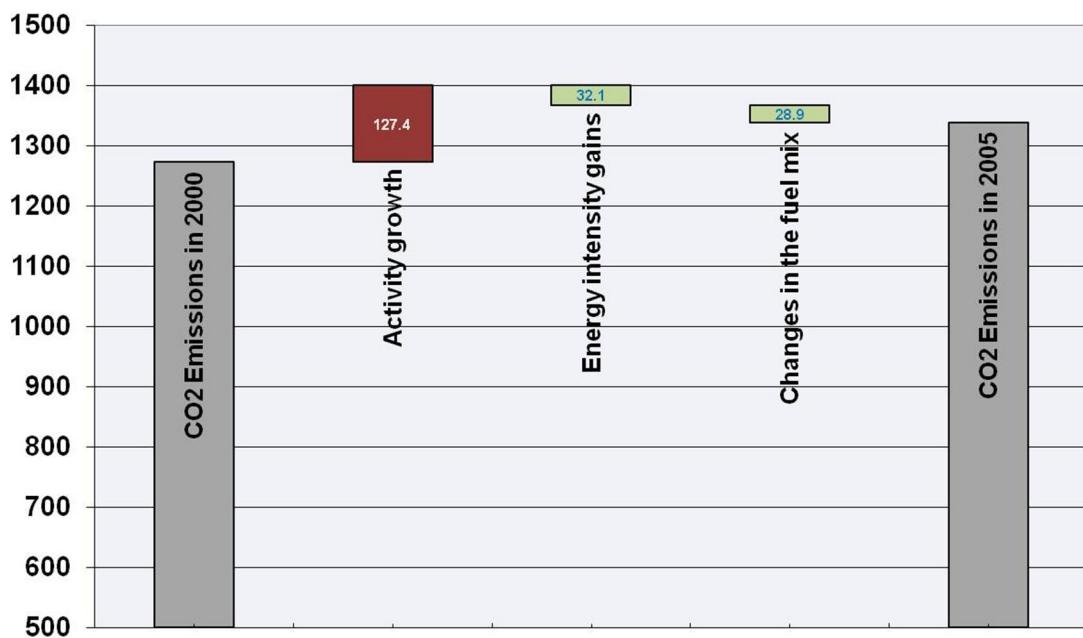

Source: PRIMES

In the power generation sector CO<sub>2</sub> emissions increased between 2000 and 2005 by 65.4 Mt CO<sub>2</sub> (+5.2%), an increase solely attributed to activity growth in the sector. This was partly counterbalanced by improvements in terms of energy intensity as well as changes in the fuel mix towards less carbon intensive energy forms (see Figure 2).

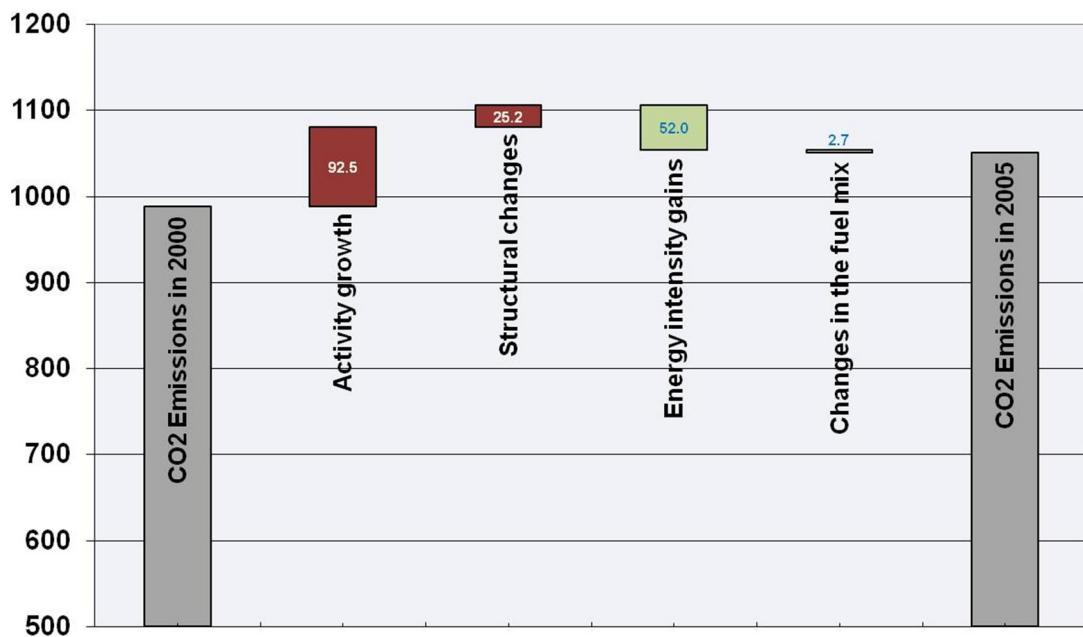

Activity growth in power generation corresponds to an increase of CO<sub>2</sub> emissions by 127.4 Mt CO<sub>2</sub>. There are three different factors driving this increase: demographic changes (population growth as well as the change of households' size) which are estimated to account for 14% of the increase, economic development which accounts for 56% of the increase and changes in the demand side fuel mix (driven by various factors such as structural changes, behavioural patterns and fuel prices) which account for the remaining 30% of the increase.

On the other hand the EU27 power generation system undergoes significant improvements both in terms of energy intensity (-32.1 Mt CO<sub>2</sub>) and changes in the fuel mix (-28.9 Mt CO<sub>2</sub>). The increasing role of natural gas in power generation (the share of which reaches 21% in 2005 from 16.8% in 2000) involving investment and operation of new efficient natural gas power plants as well as the increasing deployment of renewable energy sources (and especially wind turbines with an attributed efficiency of 100%) are the main factors that explain this development.

**Figure 2: Decomposition of CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development in power generation**

Source: PRIMES

CO<sub>2</sub> emissions in the transport sector also exhibit a significant growth in 2000-2005 (+63 Mt CO<sub>2</sub> or +6.4%). This increase is mainly driven by activity growth the contribution of which is estimated at +92.5 Mt CO<sub>2</sub> from the quantitative analysis performed. Demographic developments account for around 26.5% of this increase the rest being the result of economic growth. Structural changes in the EU transport sector (increasing role for private cars, trucks and aviation transport activity) also lead to an increase of CO<sub>2</sub> emissions in the transport sector (+25.2 Mt CO<sub>2</sub>).

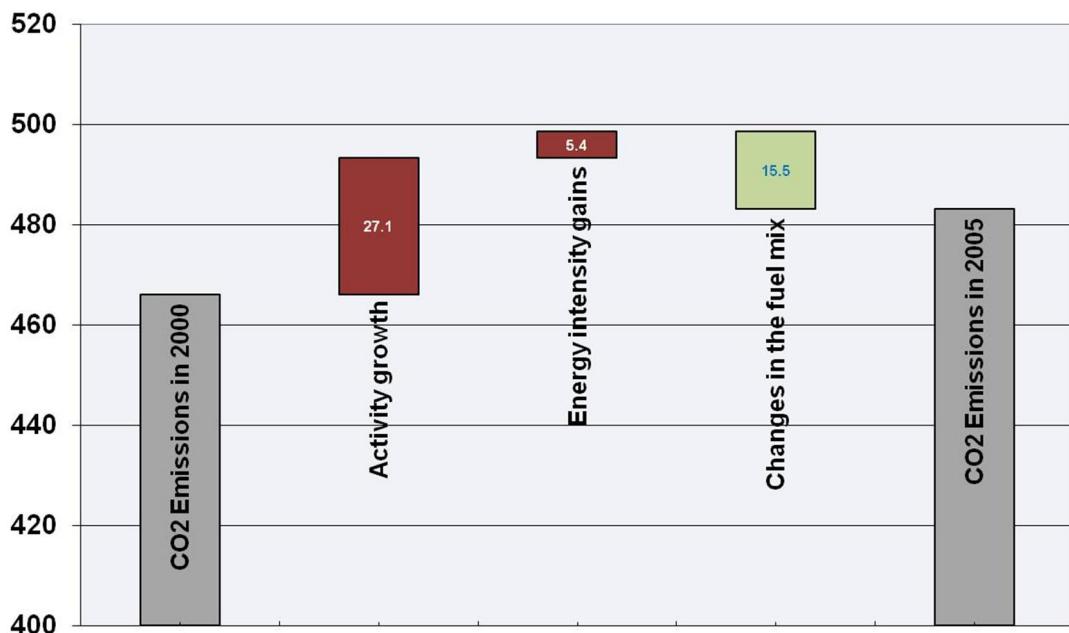

**Figure 3: Decomposition of CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development in transport**

Source: PRIMES

The purchase of more efficient vehicles (with efficiency improvements accelerated due to the implementation of the ACEA agreement) in road transport as a result of normal replacement of old stock and additional transport activity demand, the further dieselisation of the private cars stock, the continuous electrification of the rail network and the need for new airplanes (with significantly improved efficiencies compared to old ones) arising from the high growth of aviation activity, result in a significant improvement of energy intensity in the transport sector which in turn leads to an estimated reduction of CO<sub>2</sub> emissions by -52 Mt CO<sub>2</sub>. Changes in the fuel mix also lead to a limited reduction of CO<sub>2</sub> emissions in the sector (-2.7 Mt CO<sub>2</sub>), a result mainly related to the penetration of biofuels.

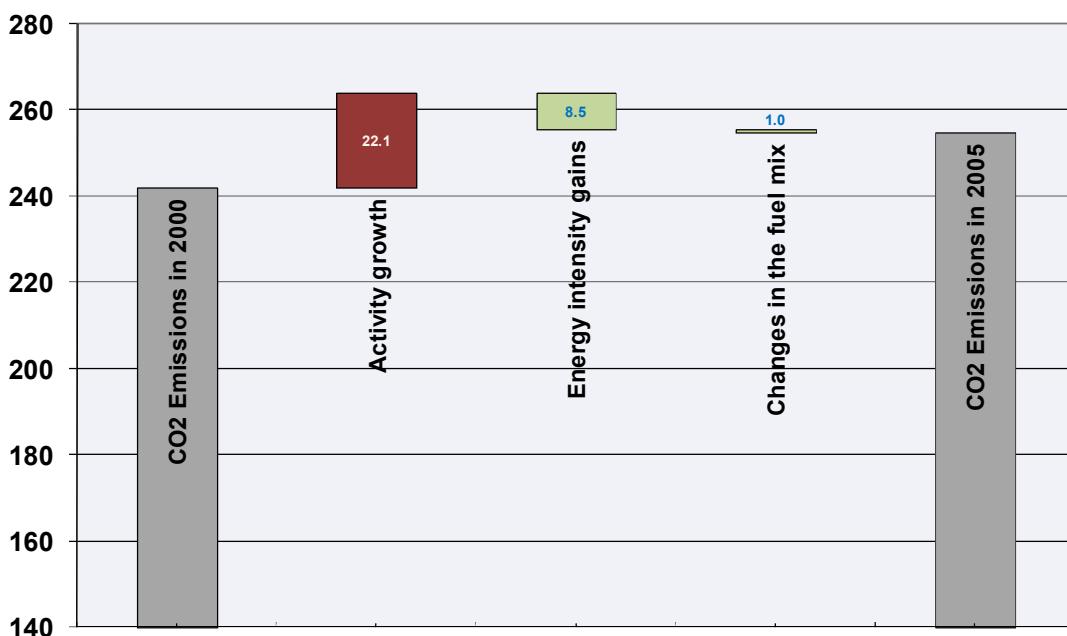

The decomposition of CO<sub>2</sub> emissions development in the residential sector is illustrated in Figure 4. Both activity growth and energy intensity gains are calculated to lead to an increase of CO<sub>2</sub> emissions (+27.1 and +5.4 Mt CO<sub>2</sub> respectively). Demographic changes account for 31% of the activity growth related increase of emissions, the rest being the result of economic growth. Energy intensity in the residential sector also worsens (consumption per household increases from 1.47 toe in 2000 to 1.49 toe in 2005) as efficiency improvements in the sector occurring both in heating/cooling uses as well as in electric appliances are not enough to counterbalance the corresponding increase of energy requirements of consumers. Changes in the fuel mix account for a reduction of CO<sub>2</sub> emissions by -15.5 Mt CO<sub>2</sub> as carbon intensity in the residential sector improves. Thus, total CO<sub>2</sub> emissions in the residential sector increase by +17 Mt CO<sub>2</sub> (or +3.6%) in 2000-2005.

**Figure 4: Decomposition of CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development in residential**

Source: PRIMES

In the tertiary sector CO<sub>2</sub> emissions exhibited an increase of +12.6 Mt CO<sub>2</sub> (+5.2%) in 2000-2005 (+14.8 Mt CO<sub>2</sub> in services and -2.2 Mt CO<sub>2</sub> in agriculture). As shown in Figure 5, energy intensity gains (-8.6 Mt CO<sub>2</sub>) and to a less extend changes in the fuel mix (-1 Mt CO<sub>2</sub>) partly counterbalanced the activity growth effect (+22.1 Mt CO<sub>2</sub>, with demographic developments accounting for 20% of the increase and economic growth for 80%) in the sector.

**Figure 5: Decomposition of CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development in tertiary**

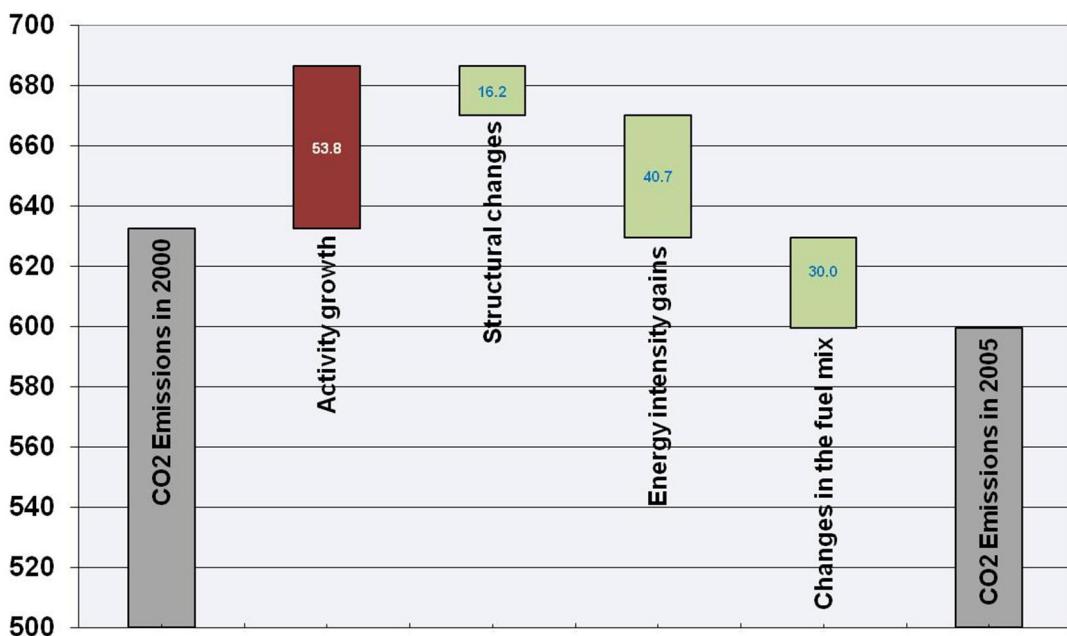

Source: PRIMES

CO<sub>2</sub> emissions in the energy branch are driven by activity growth (+12.7 Mt CO<sub>2</sub>) whereas changes in the fuel mix leading a slight improvement of carbon intensity limit the increase to 11.2 Mt CO<sub>2</sub> (+6.4%) in 2000-2005.

As regards district heating, the observed strong decline of steam production (mainly due to the restructuring of new Member States energy systems) is the key driver for the projected decline of CO<sub>2</sub> emissions in 2000-2005 (-11 Mt CO<sub>2</sub> or -23.3%). Thus, activity development in the sector has the most pronounced negative effect (-9.6 Mt CO<sub>2</sub>) followed by changes in the fuel mix (-2.2 Mt CO<sub>2</sub>) whereas some slight worsening of energy efficiency leads to an increase of CO<sub>2</sub> emissions (+0.8 Mt CO<sub>2</sub>).

CO<sub>2</sub> emissions in industry exhibit a strong decline in the period 2000-2005 (-33.0 Mt CO<sub>2</sub> or 5.3%). On the basis of activity growth effects CO<sub>2</sub> emissions from industrial sector would increase by some 53.8 Mt CO<sub>2</sub> in 2000-2005 (22% of this increase being attributed to population growth and the rest to economic developments). Structural changes (involving shifts away from energy intensive industrial sectors and towards value added intensive ones) have a negative effect on the evolution the evolution of CO<sub>2</sub> emissions (-16.2 Mt CO<sub>2</sub>). The role of energy intensity gains is even more pronounced in reducing industrial CO<sub>2</sub> emissions (-40.7 Mt CO<sub>2</sub>). Investment in more efficient technologies, the shift towards less energy intensive processes within industrial sectors (e.g. increased role for electric arc processing instead of integrated steelworks in iron and steel, significantly more pronounced growth for pharmaceuticals production compared to basic chemicals) as well as the restructuring of the industrial sector in new Member States (involving the closure or retrofitting of old inefficient industrial units but also the construction of new efficient units) are the main drivers that lead to the improvement of energy intensity in the EU energy. The changes in industrial production are also reflected on the fuel mix with demand for less carbon intensive energy forms gaining additional market shares (demand for electricity, distributed steam and biomass in industry exhibits a growth in 2000-2005 in industry compared to a decline for total industrial energy demand; demand for natural gas declines less than that for solid and liquid fuels). Thus, the carbon intensity of the EU industrial sector improves between 2000 and 2005 leading to a reduction of CO<sub>2</sub> emissions due to changes in the fuel mix by -30 Mt CO<sub>2</sub>. The decomposition of CO<sub>2</sub> developments in industry is illustrated in Figure 6.

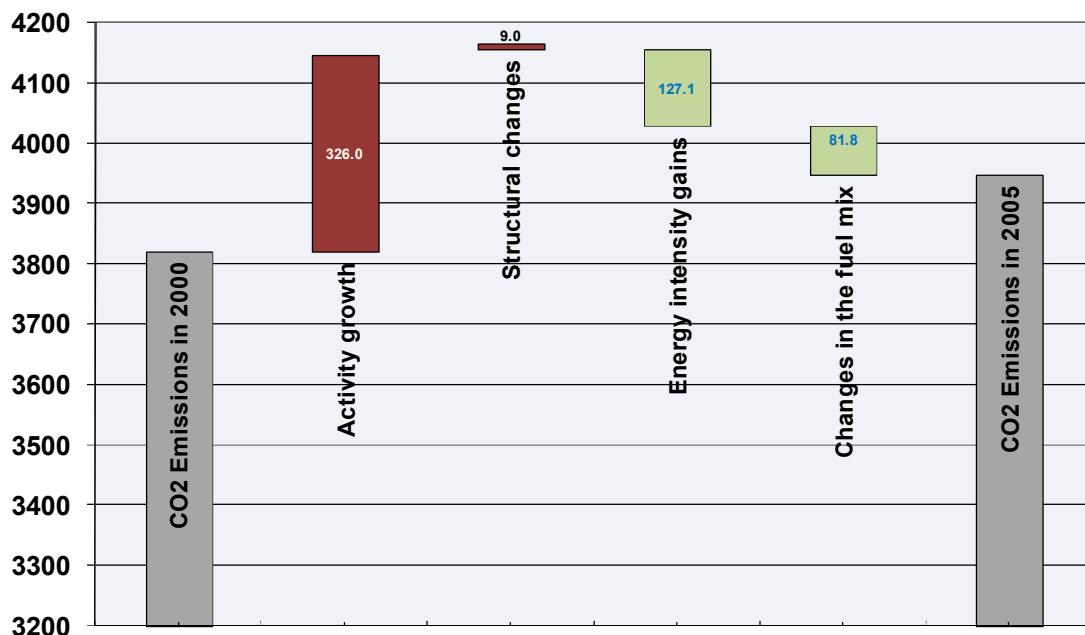

**Figure 6: Decomposition of CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development in industry**

Source: PRIMES

The overall decomposition of energy related CO<sub>2</sub> emissions growth in the EU energy system in 2000-2005, as resulting from the quantitative analysis performed with the use of the PRIMES model is illustrated in Figure 7.

**Figure 7: Decomposition of CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development for the EU energy system**

Source: PRIMES

The key driver for the observed increase of CO<sub>2</sub> emissions between 2000 and 2005 in the EU energy system is activity growth (+328 Mt CO<sub>2</sub>, of which 21.5% arises from demographic developments and the rest from economic growth). Structural changes have also a limited contribution towards increasing CO<sub>2</sub> emissions (+8 Mt CO<sub>2</sub>). On the other hand, the EU

energy system has undergone in the period 2000-2005 significant improvements both in terms of energy intensity and carbon intensity. Thus, energy intensity gains and changes in the fuel mix effects act towards reducing CO<sub>2</sub> emissions in the EU energy system (-127.1 and -81.8 Mt respectively) limiting the observed overall growth to 126.2 Mt CO<sub>2</sub>.

**Table 1: Decomposition of total energy related CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development per Member State**

	Activity growth effect	Structural changes effect	Efficiency improvement effect	Changes in fuel mix effect	Total

Source: PRIMES

Table 1 summarises the energy related CO<sub>2</sub> emissions decomposition results obtained from the quantitative analysis performed with PRIMES for all EU Member States. As can be seen in the table big differences among Member States exist as regards the role of the different factors in the development of CO<sub>2</sub> emissions. These differences relate to the different patterns of economic development, the different structures of the Member States energy systems but also the different levels of implementation of policies. Detailed decomposition results per Member State can be found in Appendix 1.

## 1.5 Impacts of key policies

In the context of the project three alternative cases were examined so as to exploit the effects of specific EU PAMs on the evolution of the energy related CO<sub>2</sub> emissions in the EU energy system between 2000 and 2005. The findings for these three cases are presented in the following.

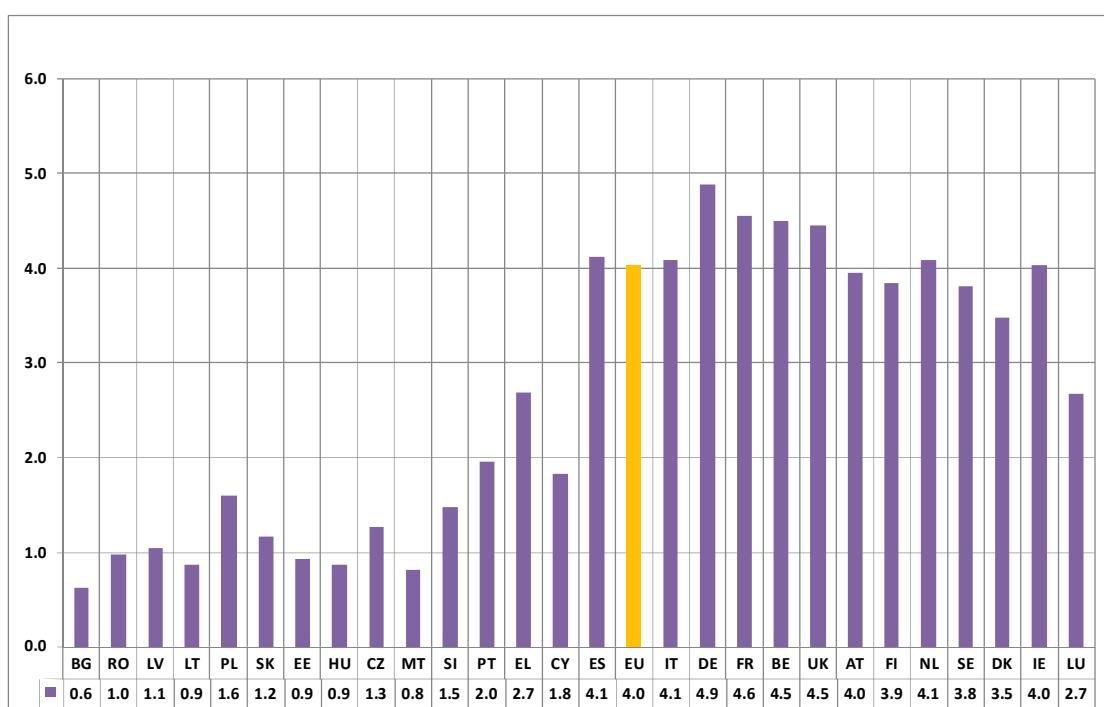

### 1.5.1 The role of the ACEA agreement

The first case examined the role that the agreement with car manufactures on lowering private cars emission factors played on the evolution of CO<sub>2</sub> emissions of the EU energy system.

This case was quantified with PRIMES by assuming that new car technologies available in the market in 2000-2005 improve at a pace similar to that historically observed and thus slower compared to observed trends. Technology and fuel choices as well as replacement rates for cars are an output of the model and thus deviate from observed statistics. In addition to the above, two important assumptions were incorporated in the analysis: first that overall transport activity and its structure remains constant at the observed 2005 levels and second that fuel prices remain unchanged to the observed 2005 levels. By introducing these two assumptions it was possible to fully capture the effects of the ACEA agreement on private cars CO<sub>2</sub> emissions without introducing side effects arising from changes in transport activity and/or fuel prices.

In the absence of the agreement with car manufactures as a driver, the improvement of cars efficiency in the EU for 2000-2005 is limited to 1% (compared to the observed improvement of 4.8%). Thus, CO<sub>2</sub> emissions from private cars in 2005 are projected to reach 501.7 Mt CO<sub>2</sub> (19.4 Mt CO<sub>2</sub> or 4.0% higher than observed statistics for 2005). The effect per Member State is illustrated in Figure 8 (in which countries are ordered by means of acceding GDP per capita).

**Figure 8: Impact of the absence of the ACEA agreement on private cars CO<sub>2</sub> emissions per Member States (% change compared to observed statistics)**

Source: PRIMES

The absence of the agreement with car manufactures results in a significantly more pronounced emissions from the EU Member States, ranging from 2.7% for Greece and Luxemburg up to 4.9% for Germany (with the exception of Portugal for which the impact is limited to only 2%). On the other hand the impact is significantly less pronounced for new Member States ranging between 0.6% in Bulgaria to 1.8% in Cyprus. This is despite the faster growth of private cars transport activity in the new Member States compared to the EU15. This is explained by the fact that the purchases of cars by consumers in new Member States concerned to a significant extent used vehicles from EU15 Member States.

Additional demand for liquid fuels leads to an increase of the operation of refineries which in turn results in higher energy requirements in the energy branch. Consequently, CO<sub>2</sub> emissions in the energy branch increase by 3.3 Mt CO<sub>2</sub> in 2005 compared to observed statistics and in power generation by 0.4 Mt CO<sub>2</sub> (due to the increased demand for electricity in refineries). In total, the effect of the implementation of the agreement with car manufactures in the EU energy system is estimated to save some 23.1 Mt CO<sub>2</sub> in 2005 (in other words CO<sub>2</sub> emissions in 2005 would be 0.6% higher than observed statistics in the absence of the agreement).

### **1.5.2 The role of the Biofuels Directive**

In the second case, the Biofuels directive, it is assumed that EU Member States do not introduce any additional policies promoting the use of biofuels in the transport sector on top of those already introduced by 2000. Given that the biofuels share in gasoline and diesel oil does not affect their price at the pump (due to the existing subsidization policies) the structure of the transport sector remains unchanged in 2005 compared to observed statistics.

In the absence of additional support policies for biofuels CO<sub>2</sub> emissions in the transport sector are projected to increase by 7.3 Mt CO<sub>2</sub> (or +0.7%) compared to observed statistics, with the total quantity of biofuels consumed being reduced to about 750 Ktoe in 2005 (compared to an observed consumption of 3,200 Ktoe).

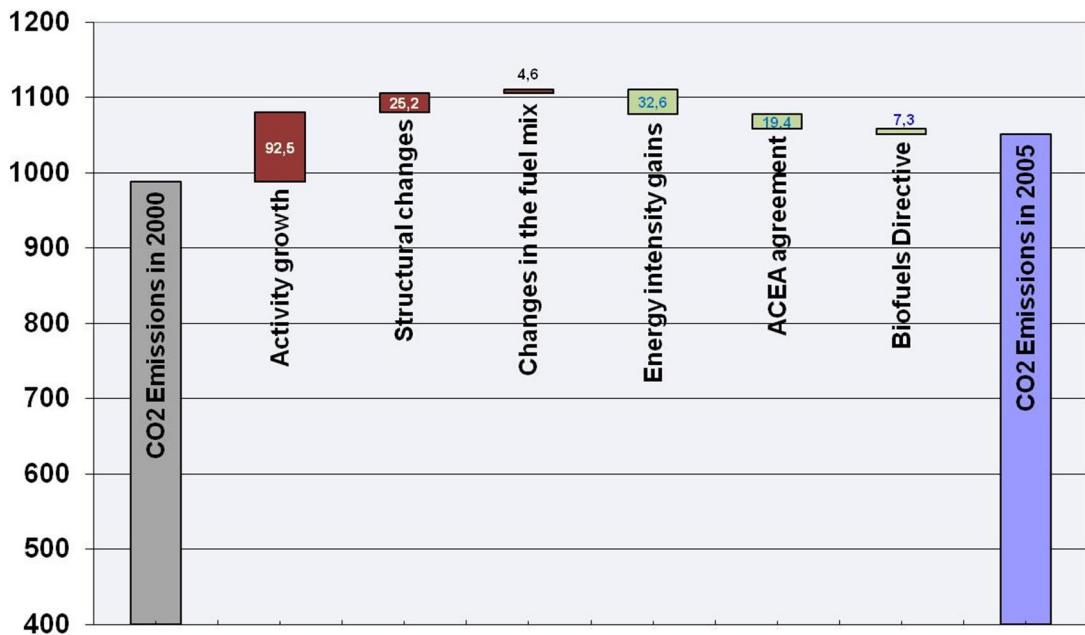

In addition, CO<sub>2</sub> emissions in the energy branch and in power generation would increase by about 0.5 Mt CO<sub>2</sub> (due to the higher operation of refineries). Thus, in the absence of additional support policies for biofuels in the EU energy system, CO<sub>2</sub> emissions in 2005 would increase by 7.8 Mt CO<sub>2</sub> (or 0.2%) from observed levels.

### **1.5.3 Revised decomposition of CO<sub>2</sub> emissions growth in transport**

Combining the results of the two cases examined, on the role of the agreement with car manufactures and on biofuels support policies, with the results of the decomposition analysis performed provides a more detailed picture for the evolution of CO<sub>2</sub> emissions in the transport sector between 2000 and 2005 (see Figure 9).

While activity growth and structural changes effects remain the same as in the initial decomposition analysis performed, the new decomposition illustrates that close to 40% of the estimated efficiency gains effect is the result of the voluntary agreement with car manufactures (19.4 Mt CO<sub>2</sub> out of 52.0 Mt CO<sub>2</sub> which is the total energy gains effects). As regards changes in the fuel mix, the Biofuels directive has an important influence on the contribution of this factors to the overall trend in emissions. With the inclusion of the support policies for biofuels changes in the fuel mix is overall estimated to have a negative effect on the evolution of CO<sub>2</sub> emissions (-2.7 Mt CO<sub>2</sub>) over the period. However, if the effect of biofuels support policies (-7.3 Mt CO<sub>2</sub>) are separated out, the effect of changes in the fuel mix on the evolution of CO<sub>2</sub> emissions in the transport sector in 2000-2005 becomes positive (+4.6 Mt CO<sub>2</sub>) This reflecting the increasing shares of diesel oil and kerosene in transport sector demand (occurring to the detriment of gasoline demand which is less carbon intensive).

**Figure 9: Revised decomposition of CO<sub>2</sub> emissions (Mt CO<sub>2</sub>) development in transport**

Source: PRIMES

#### 1.5.4 The role of the RES-E Directive

The last case examined in the context of the project with the use of the PRIMES model concerns the role of the RES-E Directive on the evolution of CO<sub>2</sub> emissions in the EU energy system in 2000-2005.

In constructing this scenario the following assumption were introduced:

- no additional support policies for renewable energy were implemented on top those existing in 2000
- electricity and steam demand is assumed not to change from observed 2005 levels (this means that changes in electricity and steam prices due to the non implementation of renewable support policies are not passed on to consumers)
- all known investment in RES that involve construction times of less than 3 years are not taken into account
- hydro power production is assumed to remain at observed levels

The introduction of these assumptions affects not only the power generation sector but also industry and district heating. This is both because of changes concerning cogeneration but also as a result of a lower deployment of biomass in industrial and district heating boilers.

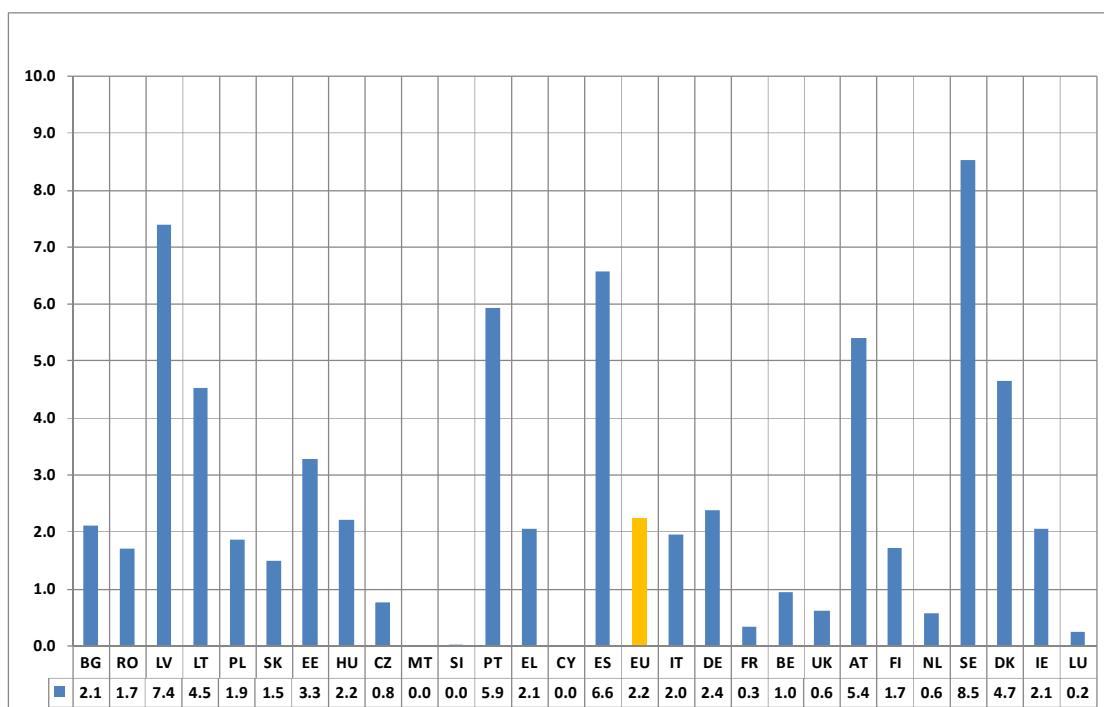

In the absence of additional support policies for renewable energy forms their share in gross electricity generation is limited to 12.1% in 2005 (from 14.5% in 2000) instead of the observed share of 14.9%. Electricity generation from wind turbines exhibits a limited growth of just 1% in 2000-2005 (compared to an observed threefold increase in the same period) while biomass based generation increases by 15% compared to an observed growth of 85%. The gap generated (around 91 TWh) is mainly satisfied by coal (42.6%) followed by natural gas (25.4%), oil (20.0%) and lignite (12%).

Electricity and steam generation from CHP power plants is also affected by the absence of renewable support policies. CHP electricity in 2005 is projected to be 9.0% below observed levels in 2005 with the corresponding decline for CHP steam reaching 7.8%. As a result of this reduced contribution of CHP units in satisfying steam requirements, generation in

industrial boilers and district heating increases. On the other hand, consumption of biomass in industrial boilers and district heating declines by 26%, limiting its share in total fuel input to 9.2% compared to an observed share of 13.4% in 2005.

Total electricity and steam generation costs are also affected by the non implementation of additional support policies for renewable energy forms; they are estimated to decline by 1.3% from observed levels in 2005.

**Figure 10: Impact of the absence of RES-E Directive support policies on total energy system CO<sub>2</sub> emissions per Member States (% change compared to observed statistics)**

Source: PRIMES

In the absence of support policies for renewable energy, total energy related CO<sub>2</sub> emissions in 2005 are projected to reach 4,036 Mt CO<sub>2</sub> (+88.7 Mt CO<sub>2</sub> or +2.2% compared to observed CO<sub>2</sub> emissions levels in 2005). CO<sub>2</sub> emissions in power generation are projected to increase by 58.0 Mt CO<sub>2</sub> (+4.3% from observed statistics), in industry by 19.6 Mt CO<sub>2</sub> (+3.3%) and in district heating by 11.1 Mt CO<sub>2</sub> (+30.5%). The effect for total energy related CO<sub>2</sub> emissions per Member State is illustrated in Figure 10 (in which countries are ordered by means of acceding GDP per capita).

## 1.6 Synthesis and conclusions

The PRIMES model has been used to quantify the key drivers of energy-related emissions of CO<sub>2</sub> within the EU between 2000 and 2005, as well as estimating the ex-post savings arising from selected climate change policies.

The analysis has been based upon a decomposition methodology whereby each of the individual drivers of energy use and CO<sub>2</sub> emissions have been isolated, thereby demonstrating the relative influence of each of the drivers on the overall trend.

The main findings from the analysis are as follows:

- Between 2000 and 2005 energy related CO<sub>2</sub> emissions in the EU27 energy system increased from 3,820 Mt CO<sub>2</sub> to 3,947 Mt CO<sub>2</sub> (+126.2 Mt CO<sub>2</sub> or +3.3%). Power generation and the transport sector were the main drivers for this increase of CO<sub>2</sub> emissions whereas the most pronounced decline of CO<sub>2</sub> emissions was observed in industry.
- EU policies and measures had an important role in slowing down the growth in emissions over this period. The combined effect of the EU Voluntary Agreement with car manufacturers and the implementation of the Biofuels and the RES-E Directives is an estimated reduction of CO<sub>2</sub> emissions of 120 Mt CO<sub>2</sub>. In other words, and on the basis of PRIMES results in the absence of these policies, CO<sub>2</sub> emissions in 2005 would have reached 4,067 Mt CO<sub>2</sub> (+6.4% from 2000 levels, +3.0% from observed 2005 levels).

In relation to the broader objectives of the study, the following conclusions can be drawn:

- **Development of methodologies**

Existing models, such as PRIMES, which have been developed with the primary role of appraising the projected impacts of new policies, also have the potential to be modified for use in the ex-post evaluation of existing policies. A major strength of this approach is that, where the model in question was used for the original ex-ante analysis, it allows a consistent and comparable assessment of the differences between the ex-ante and ex-post estimates.

However, unless it was a specific requirement at the design stage, existing models may not have been constructed with ex-post evaluation in mind. It may therefore be appropriate, when commissioning the development of new models, for the EU Commission to give consideration to the use of the models in ex-post evaluation, as well as in the ex ante appraisal of new policies.

In doing so, it is important to understand the relative strengths and weaknesses of the different modelling tools. In particular, ex-post studies generally look at impacts arising over a relatively short period of time, so may not be best suited to econometric models that draw upon long term statistical trends.

- **Provision of quantitative ex-post estimates**

The PRIMES model provided an existing framework, including an existing database of activity and emissions data, and modelling relationships. This made the quantitative assessment of the policy impacts possible without the need for further data collection - although it did require certain modifications to the model to be made.

The modelling has delivered quantitative estimates of the ex-post impacts of three EU climate policies: the ACEA Voluntary Agreement, the Biofuels Directive and the RES-E Directive. Each of these policies has a number of common themes. They all act upon a single target sector (road transport, renewable energy). Data on the activities that are influenced by the Directives (vehicle emissions, biofuel consumption, and renewable electricity) is readily available from existing statistical sources. In addition, each of the policies can be considered

the primary mechanism targeting emissions in its respective sector. These factors combine to make it easier to evaluate the impacts of these policies than for certain other policies.

Analysis of the other energy policies would require additional data collection and more substantive modifications to the modelling framework. This was not possible within the scope of the study. In any case, the PRIMES model may not be the best framework within which to quantify the impacts of these policies. In particular, where data is required at a greater level of resolution, for example at a sub-sectoral level, more bespoke sectoral models might be more appropriate.

- **Recommendations for future ex-ante appraisal**

For each of the policies analysed the PRIMES modelling has identified the key issues and assumptions that have influenced the results of the evaluation. It is important that these factors are considered within future policies appraisals, where appropriate. For example, in the evaluation of the ACEA agreement for passenger cars, differences in purchase behaviour led to difference in the impacts of the policy within different Member States. It would be important to consider these behavioural factors in the ex-ante appraisal of future transport policies.

- **Capacity building**

The PRIMES model is a multi-country, multi-sector model. This provides advantages in that it allows the assessment of EU wide initiatives across all Member States in a consistent and coherent manner. It can also provide efficiencies; the assessment of interventions is a collective manner is more efficient than aggregating together a range of individual Member State or sector estimates. A downside of this approach is that the modelling capacity remains within a single institution with limited scope for capacity building elsewhere. This strand of the project has therefore had limited impact upon this objective.
